About this course

Course Content

This course builds on introductory R and expands on essential concepts for R. We cover common problems in data manipulation to pre-process datasets and we will cover some visualization. 99.5% of a data scientist's job is data pre-processing and visualization. The rest is analysis. Therefore, brushing up on programming skills in R makes the experience of working with R a lot more enjoyable.

Course Objectives

Participants will learn data manipulation skills such as merging data, re-shaping it, aggregating it and more. Course participants should be a lot more comfortable in working with R upon completing this course.

Course Prerequisites

Participants are expected to have used R and RStudio before.

Agenda

- 1. Data sub-setting, logical conditions, missing values, simple plots
- 2. Tidyverse introduction: Simple data manipulation, renaming, summarizing, aggregating
- 3. Merging data
- 4. Reshaping data
- 5. Regular expressions

Acknowledgements

The ESRC Business and Local Government Data Research Centre is funded by the Economic and Social Research Council (ESRC).

1 Data sub-setting and logical conditions

1.1 Learning objectives

In this exercise, we will talk about sub-setting data sets, i.e. findings interesting observations and variables that we want to describe. Furthermore, we will introduce logical conditions in R. Logical conditions are often necessary for data wrangling.

1.1.1 Sub-setting

When we deal with data sets and vectors such as data set's rows or columns, we want to be able to subset these objects. Sub-setting means, we access a specific part of the data set or vector. R comes with some small data sets included. The macroeconomic data set longley is one such data set. Lets have a look at what the data set contains by using the help files:

?longley

A data set is two-dimensional. It's first dimension are the rows. A 5 on the first dimension, therefore, means row 5. On the second dimension, we have columns. A 4 on the second dimension refers to column 4. We can identify each individual element in a data set by it's row and column coordinates. In R, we subset using square brackets [row.coordinates, column.coordinates]. In the square brackets, we place the row coordinates first, and column coordinates second. The coordinates are separated by a comma. If we want to see an entire row, we leave the column coordinate unspecified. The first row of the longley data set is:

```
longley[1,]
```

```
GNP.deflator GNP Unemployed Armed.Forces Population Year Employed 1947 83\ 234.289 235.6 159 107.608 1947 60.323
```

The second column is:

```
longley[ , 2 ]
```

- [1] 234.289 259.426 258.054 284.599 328.975 346.999 365.385 363.112
- [9] 397.469 419.180 442.769 444.546 482.704 502.601 518.173 554.894

The element in the first row and second column is:

```
longley[ 1 , 2 ]
```

[1] 234.289

We can view a number of adjacent rows with the colon operator like so:

```
longley[1:5,]
```

	${\tt GNP.deflator}$	GNP	Unemployed	Armed.Forces	Population	Year	Employed
1947	83.0	234.289	235.6	159.0	107.608	1947	60.323
1948	88.5	259.426	232.5	145.6	108.632	1948	61.122
1949	88.2	258.054	368.2	161.6	109.773	1949	60.171
1950	89.5	284.599	335.1	165.0	110.929	1950	61.187
1951	96.2	328.975	209.9	309.9	112.075	1951	63.221

We can view a number of non adjacent rows using the vector function c() like so:

```
longley[ c(1,3,5), ]
```

```
GNP.deflator
                       GNP Unemployed Armed. Forces Population Year Employed
1947
             83.0 234.289
                                 235.6
                                               159.0
                                                        107.608 1947
                                                                        60.323
1949
             88.2 258.054
                                 368.2
                                               161.6
                                                        109.773 1949
                                                                        60.171
1951
             96.2 328.975
                                 209.9
                                               309.9
                                                        112.075 1951
                                                                        63.221
```

Furthermore, columns in data sets have names. These are the variable names. We can obtain a list of variable names with the names() function.

```
names(longley)
```

```
[1] "GNP.deflator" "GNP" "Unemployed" "Armed.Forces" [5] "Population" "Year" "Employed"
```

This returns a vector of names. You may have noticed the quotation marks. Whenever you see quotation marks in R, you know this refers to a text. There are different storage or data types. Examples are numeric and character (text).

We can use the name of a variable for sub-setting a data set. Suppose, we want to see the population variable. We can either use 5 in square brackets because population is the 5th column or we can place the variable name within quotation marks in the brackets.

```
longley[ , "Population"]
```

```
[1] 107.608 108.632 109.773 110.929 112.075 113.270 115.094 116.219
```

[9] 117.388 118.734 120.445 121.950 123.366 125.368 127.852 130.081

To access multiple variable columns by the variable names, we have to use the vector function c() like so:

```
longley[ , c("GNP", "Armed.Forces", "Population") ]
```

	GNP	${\tt Armed.Forces}$	Population
1947	234.289	159.0	107.608
1948	259.426	145.6	108.632
1949	258.054	161.6	109.773
1950	284.599	165.0	110.929
1951	328.975	309.9	112.075
1952	346.999	359.4	113.270
1953	365.385	354.7	115.094
1954	363.112	335.0	116.219
1955	397.469	304.8	117.388
1956	419.180	285.7	118.734
1957	442.769	279.8	120.445
1958	444.546	263.7	121.950
1959	482.704	255.2	123.366
1960	502.601	251.4	125.368
1961	518.173	257.2	127.852
1962	554.894	282.7	130.081

Finally, we can also access a column in a data set using the dollar sign operator \$ like so:

longley\$Population

```
[1] 107.608 108.632 109.773 110.929 112.075 113.270 115.094 116.219
```

```
[9] 117.388 118.734 120.445 121.950 123.366 125.368 127.852 130.081
```

The population column is a vector. Vectors are 1-dimensional. We can subset vectors in the same way that we subset data sets except that we only need 1 coordinate to uniquely identify every element. Let's access the first element in the population column in three different but equivalent ways.

```
# option 1s
longley$Population[1]

[1] 107.608
# option 2
longley[1 , 5]

[1] 107.608
# option 3
longley[1 , "Population"]
```

[1] 107.608

Finally, two useful sub-setting tricks:

- 1. the operator means except and can be used to view all elements except the one specified
- 2. with the length() function we can find the last element of a vector

So, all rows in the longley data set except the first 5 would be:

```
longley[ -1 : -5, ]
```

	GNP.deflator	GNP	Unemployed	Armed.Forces	Population	Year	Employed
1952	98.1	346.999	193.2	359.4	113.270	1952	63.639
1953	99.0	365.385	187.0	354.7	115.094	1953	64.989
1954	100.0	363.112	357.8	335.0	116.219	1954	63.761
1955	101.2	397.469	290.4	304.8	117.388	1955	66.019
1956	104.6	419.180	282.2	285.7	118.734	1956	67.857
1957	108.4	442.769	293.6	279.8	120.445	1957	68.169
1958	110.8	444.546	468.1	263.7	121.950	1958	66.513
1959	112.6	482.704	381.3	255.2	123.366	1959	68.655
1960	114.2	502.601	393.1	251.4	125.368	1960	69.564
1961	115.7	518.173	480.6	257.2	127.852	1961	69.331
1962	116.9	554.894	400.7	282.7	130.081	1962	70.551

We can get the length of a vector using the length() function like so:

```
length( longley[, 1] )
```

[1] 16

That is the length of the first column in the longley data set and because a data set is rectangular it gives us the number of rows in the data set as well. We get the last row in the longley data set like so:

```
longley[ length( longley[ , 1] ) , ]
```

```
GNP.deflator GNP Unemployed Armed.Forces Population Year Employed 1962 116.9 554.894 400.7 282.7 130.081 1962 70.551
```

To get the last element in the population vector of the longley data set, we would code:

```
longley[ length(longley[,1]), "Population" ]
```

```
[1] 130.081
```

There are often many different approaches that will do the same thing. In does not matter how you get to a solution as long as get there. For instance, the nrow() function returns the number of rows in a data set or matrix object. So we could get the last element in the population vector using nrow() instead of length():

```
longley[ nrow(longley), "Population" ]
```

```
[1] 130.081
```

Sub-setting is essential for understanding data and manipulating it.

Finding the last column of the longley data set can be done using the ncol() function. The function returns the number of columns in the object that is supplied to the function. If we use that number in sub-setting, we can access the last column.

```
longley[ , ncol(longley) ]
```

```
[1] 60.323 61.122 60.171 61.187 63.221 63.639 64.989 63.761 66.019 67.857 [11] 68.169 66.513 68.655 69.564 69.331 70.551
```

1.1.2 Logical conditions

We now load regional data from the European Union from the Quality of Government Institute to illustrate logical conditions and dealing with missing values. The data set is very large in the sense that it contains many different columns (variables)

Download Data

A full codebook of the data set is available online (codebook)

```
eu <- read.csv("qog_eureg_long_sep16.csv", stringsAsFactors = FALSE)</pre>
```

Before, we start working with the data set, do the following tasks on your own:

- 1. check the dimensions of eu
- 2. check the first 15 variable names of the data set
- 3. print the rows 120 to 130 of the data set and the following variables: "NUTS0", "region_name" and econ_2gdp_eur_hab (country name, region name, per capita wealth at current prices)

If you are unsure about a function that you need to complete this task, try looking for it online. For example, googling "R find names of a data set" will get you to the function that you need for solving this problem. R does have a steeper learning curve than more traditional data software like Excel. Therefore, it is good practice to get into the habit of searching and learning how to quickly find answers online.

Wien

The dim() function returns two numbers. The first is the number of rows and the second is the number of columns (if the object is two-dimensional). The function could also be used on arrays in which case it would also return the number of layers. We could have also found the number of rows using nrow() and the number of columns using ncol(). Or we could have used the length() function with sub-setting. For example, length(eu[,1]) returns the length of the first column of the u which is equal to the number of rows in the dataset. Equally, length(eu[1,]) returns the length of the first row which is equal to the number of columns.

The names() function can be used on several objects such as data frames and lists. Here, names() returns the column names of the data set. In the case that you are dealing with a matrix instead of data frame — you can assess this by using is.data.frame() and is.matrix() — you would use the columns () function for the column names. Here, we have so many variables that names() would fill our screen with a very long vector of variable names. Therefore, we subset the names vector to only display the first 5 variable names

We use [] for sub-setting. So eu[1:6, 1:4] returns the first six rows and the first four columns of the data set.

```
# the dimensions: rows (observations) and columns (variables)
dim(eu)
[1] 13884
            444
# the variable names
names(eu)[1:15]

We now move to using logical conditions. Generally, R works with the following relational operators:

Operator	Effect
==	Equal to
!=	Not equal to
<	Less than
>	Greater than
<=	Less than or equal to
>=	Greater than or equal to

In addition to these, we also have logical operators at our disposal, for example to chain relational operations together. Let's say we are interested in all nations where GDP is greater or equal to the first quartile and

smaller or equal to the median. To do that we need the logical "AND" operator.

There are essentially two logical operators: (1) AND, (2) OR. We can perform these element-wise or only using the first observations. If we want to compare vectors, the and operator & compares all vector elements and the && operator compares the first elements.

Operator	Effect
!	Logical NOT
&	Element-wise logical AND
&&	Logical AND
	Element-wise logical OR
	Logical OR

To illustrate the difference between element-wise operations and evaluating the first element only, we create two vectors \mathbf{x} and \mathbf{y} .

```
x <- c( TRUE, TRUE, FALSE, FALSE )
y <- c( FALSE, TRUE, FALSE, FALSE)
# element-wise AND
x & y</pre>
```

[1] FALSE TRUE FALSE FALSE

```
# first observations AND
x && y
```

[1] FALSE

We see that the difference is which elements of a vector are to be compared. Usually we use element wise comparison. Furthermore, we can use the functions all() and any() to evaluate whether all elements of a vector are the same or whether any element is different (we could use both all() and any() for this).

On your own, compare whether all elements are the same in x and y.

Reveal content

```
all(x == y)
```

[1] FALSE

The answer is that the vectors x and y differ in some elements. Let's find out where the differences lie.

Let's assume we want to know which elements of two vectors are equal. This is often necessary for merging data sets. Let's say we have two data sets and both contain the string "UK" as a country identifier for the United Kingdom. We now want to know which observations in both data sets refer to the UK. We can do this with relational operators and the which() function. Lets' get back to our mini-example. We want to compare which elements of x are different from the elements in y. Try to do this on your own.

```
which(x != y)
```

[1] 1

Notice that our code compares the first element of x with the first element of y, the second element of x with the second element of y and so on.

Let's apply our knowledge to the eu data set. You have the following tasks.

- 1. Check which countries our data set contains (hint: use either the table() function or the unique() function)
- 2. Check which years our data set contains (hint: use either the table() function or the unique() function on the variable year)

- 3. Generate a data set called uk which contains only regions from the United Kingdom.
- 4. Produce descriptive statistics for the wealth variable econ_2gdp_eur_hab (GPD per person by current
- 5. Display the observations that are above the median up until and including the third quartile in the year 2014 (only show the variables region_name and econ_2gdp_eur_hab).

```

The data set is quite messy. You can see that R displays a first column with strange content. These are row names and have no further significance for us. The row names carry over from the original eu data set. You can view the vector of row names by running the following R code:

<NA>

<NA>

<NA>

Highlands and Islands

NΑ

NA

NA

29900

1.1.3 Re-naming variables

We want to rename econ_2gdp_eur_hab into something more meaningful. The new name should be wealth. We can use the names() function to get a vector of variable names like so: names(eu).

We want to change the element of that vector which is econ_2gdp_eur_hab and we need the which() function to achieve this. Try to solve the problem on your own.

```
which( names(eu) == "econ_2gdp_eur_hab")
```

Γ17 36

Great, now we know which column to look at. Now to rename the variable

```
names(eu)[ which( names(eu) == "econ_2gdp_eur_hab") ] <- "wealth"</pre>
```

We now check the variable names to confirm that we successfully changed the name.

```
names(eu)[36]
```

[1] "wealth"

1.1.3.1 Missing data

Let's have a look at the summary function on the wealth variable within the eu data set.

```
summary(eu$wealth)
```

```
Min. 1st Qu. Median Mean 3rd Qu. Max. NA's 1300 14600 23800 23450 30000 172600 7896
```

The summary() function informs us that there are 7896 missing values. We cannot calculate with missing values. For instance, mean(eu\$wealth) will return NA unless we specifically instruct the mean() function to ignore missing values like so: mean(eu\$wealth, na.rm = TRUE). Some functions like lm() will just throw out missing values without informing us. Whenever we use wealth in calculation, we must remove missing values or fill in some estimates for the missing values.

Should we remove missing values from our data sets before carrying out analysis? The answer is, it depends we should never remove missing values from variables that we are not interested in. The reason is that, we must keep the rectangular structure of data set intact. We therefore delete entire rows from our data set whenever we delete a missing value. If an observation is recorded for a variable we are interested in but missing for a variable that we are not interested in, then removing missings on the un-interesting variables would unnecessarily remove a recorded observation from a variable we are interested in.

However, removing missing values from a variable that we are interested in is fine. Remember though that statistical analyzes become less accurate (variance increases and bias may increase) through list-wise deletion. For statistics, imputing (estimating) missing values is often a better solution. We remove missing values from the wealth variable.

The function is.na() returns TRUE or FALSE for every element in the vector that we supply where TRUE means that the value is missing. We could reverse is.na() to mean is not NA like so: !is.na().

Try this on your own. But combine it with the table() function. So that instead of getting a very long vector of TRUE/FALSE we see the number of missings and non-missings.

```
table(!is.na(eu$wealth))
```

```
FALSE TRUE 7896 5988
```

We can subset our data set to include only those observations that are not missing. Try this on your own:

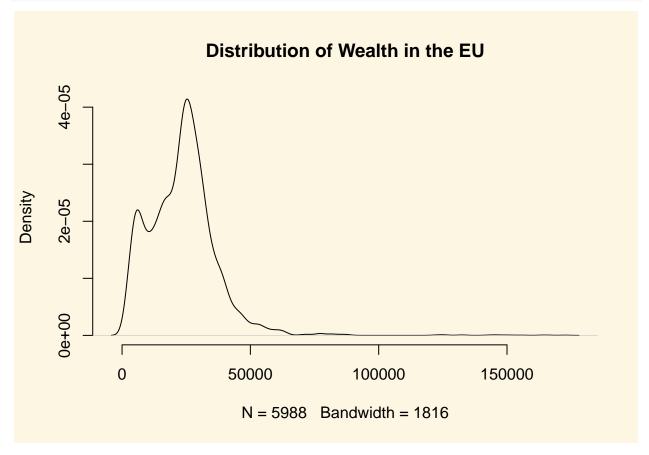

```
eu <- eu[!is.na(eu$wealth), ]
```

We have now successfully removed missing values from the wealth variable which will make working with the variable a lot easier. We produce a few simple plots to describe our data which would require a lot more code had we not removed missing values.

1.1.3.2 Simple plots

With the missing values removed from the wealth variable, we can now easily plot the distribution of that variable. The density() function will estimate the density of a variable which we can combine with the plot() function to give us an idea about the general distribution of that variable.

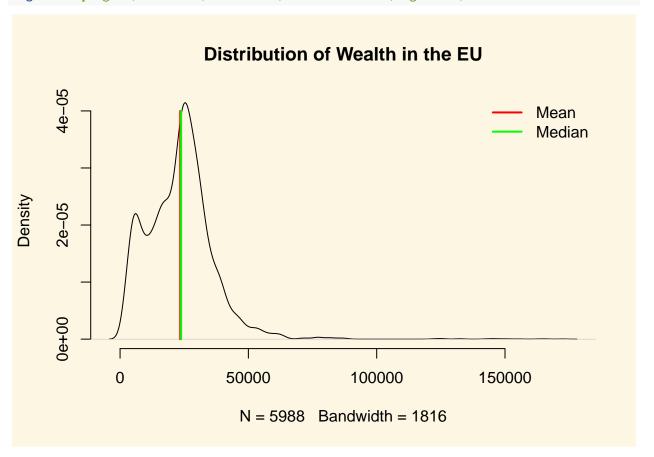

```
plot(
  density(eu$wealth),
  bty = "n",
  main = "Distribution of Wealth in the EU"
)
```

Is this distribution right-skewed or positively skewed? Put differently, are there a few observations that are very wealthy but most are not? To illustrate let's add both the median and the mean to the plot. Recall that

the mean is susceptible to outliers and hence in a right-skewed distribution the mean is greater than the median.

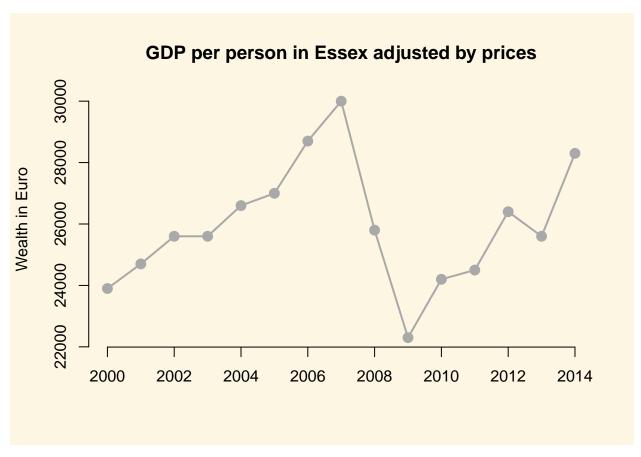

```
lines(x = rep(mean(eu$wealth),10), y = seq(0, 4e-05, length.out = 10), col = "red", lwd = 2)
lines(x = rep(median(eu$wealth),10), y = seq(0, 4e-05, length.out = 10), col = "green", lwd = 2)
legend("topright", c("Mean", "Median"), col = c("red", "green"), lwd = 2)
```

In this case median and mean are relatively close together, pointing to a relatively symmetric distribution. Keep in mind though that our unit of observation is the region-year. For instance, Essex in 1994.

Let's plot over-time development of wealth in Essex. On the x-axis, we plot time and on the y-axis, we plot wealth.

```
plot(
    x = eu$year[eu$region_name=="Essex"],
    y = eu$wealth[eu$region_name=="Essex"],
    xlab = "",
    ylab = "Wealth in Euro",
    main = "GDP per person in Essex adjusted by prices",
    bty = "n",
    col = "darkgrey",
    pch = 16,
    cex = 1.5
)
lines(x = eu$year[eu$region_name=="Essex"],
          y = eu$wealth[eu$region_name=="Essex"],
          lwd = 2,
          col = "darkgrey")
```

It seems that per person wealth in Essex was not quite back at pre financial crisis levels in 2014. We might want to compare Essex to the rest of the UK. Doing so efficiently means that we have to aggregate wealth data to the UK level for each year. We could write code for this but doing such manipulations is one strong suits of the tidyverse which we introduce in the next part of this course.

2 Tidyverse introduction

2.1 Seminar

2.1.1 Introduction to the tidyverse

The tidyverse package makes it easier to pre-process data. The package attempts to make it easier to apply operations that would otherwise require a substantial amount of coding. The syntax of the tidyverse is meant to be more intuitive than base R syntax but that also means that you have to learn new syntax. Working with the tidyverse is a matter of taste. A great resource for learning tidyverse and R is the book R for data science which is freely available.

Before getting started, we first need to install the tidyverse package like so: install.packages("tidyverse"). You only need to install once. However, doing this again is not a mistake. In fact, R, RStudio and R packages are regularly updated. It is good practice to update all of these on your computer as well. Just remember never to update before a deadline!

```
# clear workspace
rm(list = ls())
# load tidyverse package
library(tidyverse)
```

Let's check whether we have updates available by runing tidyverse_update()

```
# check for available updates
tidyverse_update()
```

The following packages are out of date:

```
* httr (1.4.0 -> 1.4.1)
* modelr (0.1.4 -> 0.1.5)
* tidyr (0.8.3 -> 1.0.0)
* xml2 (1.2.0 -> 1.2.2)

Start a clean R session then run:
install.packages(c("httr", "modelr", "tidyr", "xml2"))
```

R tells us that several packages are in indeed out of data (this may be different on your computer - it's possible that everything is up to date on your machine). Below, we update according to the console message.

```
install.packages(c("httr", "modelr", "tidyr", "xml2"))
tidyverse_update()
```

All tidyverse packages up-to-date

Now, everything is updated correctly.

Let's re-load the EU data set that we used previously.

Download Data

```
eu <- read.csv("qog_eureg_long_sep16.csv", stringsAsFactors = FALSE)</pre>
```

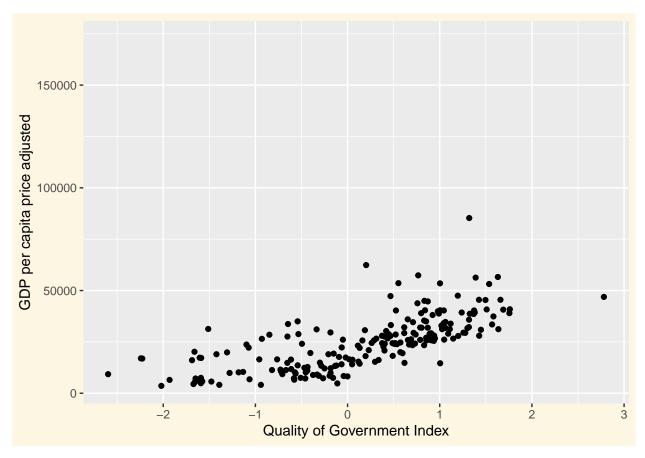

2.1.2 Data visualization with ggplot2

In the previous exercise, we stopped on data illustration. Base R graphics is very powerful and you can do almost anything with it. However, it does require to write a lot of code. ggplot2 is useful because it helps us to produce good looking graphics with relative ease.

Let's create a simple scatter plot. We use the wealth variable <code>econ_2gdp_eur_hab</code> and the European Quality of Government Index (EQI) — variable name <code>eqi_eqi</code> — to assess whether the two are related but only for post 2010.

```
ggplot(data = eu[eu$year >2010,]) +
   geom_point(mapping = aes( x = eqi_eqi, y = econ_2gdp_eur_hab)) +
   labs(x = "Quality of Government Index", y = "GDP per capita price adjusted")
```

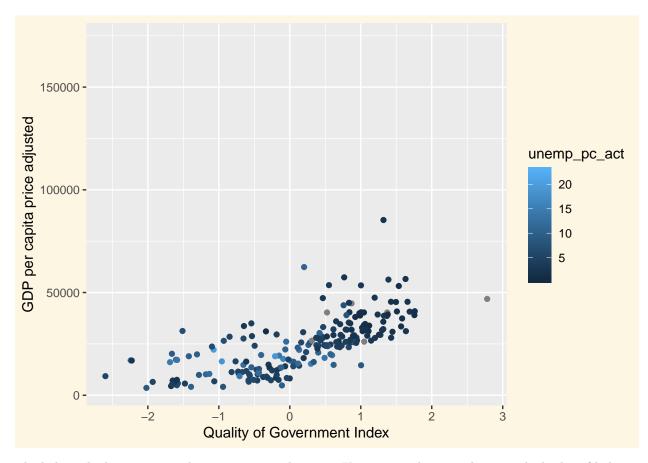

Warning: Removed 2464 rows containing missing values (geom_point).

The plot looks a bit better than what we produced with base R. We also spot a slightly positive relationship. Let's walk trough the code. First, we type ggplot() which creates the coordinate system which we then add layers to. The argument that we supply to ggplot() is the data we are using. The code ggplot(data = eu) creates an empty plot. We then add the points or observations to the plot with the function geom_point(). The argument mapping is necessary for ggplot to decide how variables are mapped to visuals. mapping is always paired with aes() as well as the x and y arguments which just like in base R's plot() function correspond to the axes. Recall that it is convention to place the independent variable on the x axis and the dependent variable on the y axis.

Let's add a third variable to the plot. Here, we use labor market statistics. The variable unemp_pc_act measures long-term unemployment as percentage of the active population. We use the variable for the color argument.

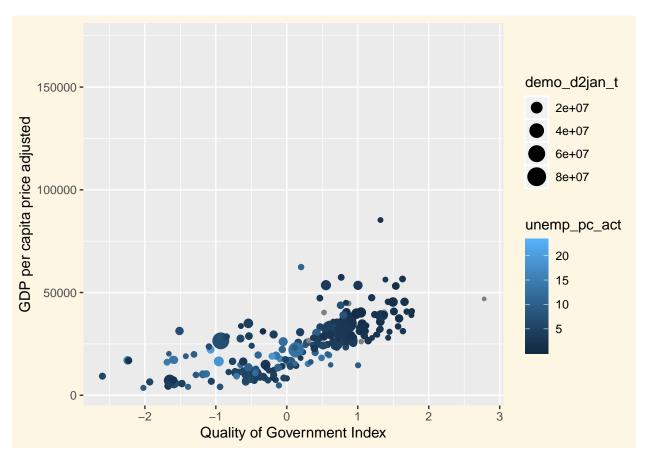

Warning: Removed 2464 rows containing missing values (geom_point).

The lighter shading corresponds to more unemployment. Using unemployment does not shed a lot of light on the relationship between the variables. It does seem like places with more unemployment cluster at the lower end of the governance index and they correspond with less per capita wealth which is to be expected.

Instead of using a third variable on color, we could use it on the size of the points. For instance, population size is often applied here, making larger units more prominent. Let's use the total population variable for the size of the points.

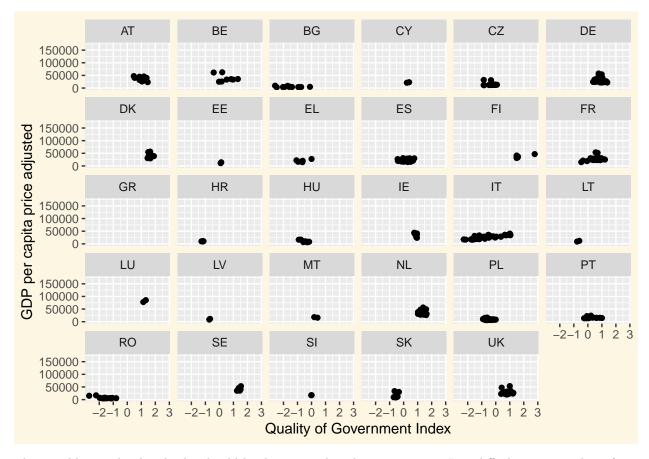

Warning: Removed 2464 rows containing missing values (geom_point).

Let's evaluate whether the relationship between the governance index and wealth holds within countries. We can use **facets** to create multiple plots where the splots are split by a variable like, for instance, country.

```
ggplot(data = eu) +
  geom_point(mapping = aes( x = eqi_eqi, y = econ_2gdp_eur_hab)) +
  facet_wrap(~ NUTSO, nrow = 5)
```

Warning: Removed 13469 rows containing missing values (geom_point).

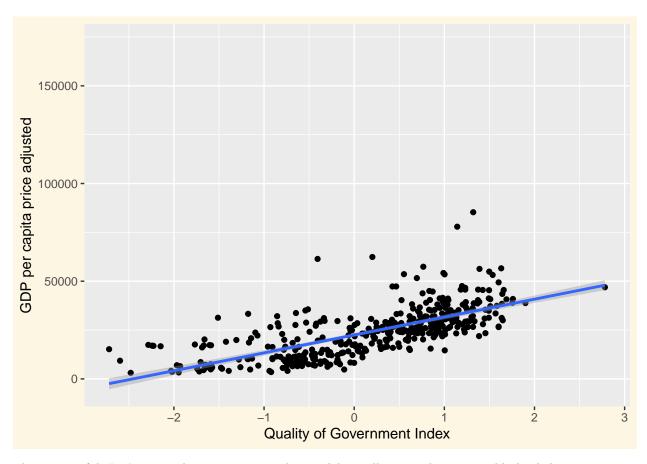

The variable to split the plot by should be discrete rather than continuous. It is difficult to see much on facet plots, when the splitting variable has many categories as in this case. We see, however that especially in Italy there are large differences between the quality of governance.

In our initial plot, we were interested in the relationship between governance and the wealth. Let's add a linear regression line including the confidence interval to the plot.

```
ggplot(eu, aes(x = eqi_eqi, y = econ_2gdp_eur_hab)) +
  geom_point() +
  geom_smooth(method = lm) +
  labs(x = "Quality of Government Index", y = "GDP per capita price adjusted")
```

Warning: Removed 13469 rows containing non-finite values (stat_smooth).

Warning: Removed 13469 rows containing missing values (geom_point).

This was useful. Let's say we have a more complex model. To illustrate this, we quickly load the world.data data set.

Download Data

```
world.data <- read.csv("QoG2012.csv")</pre>
```

Now, we regress quality of life measured by the United Nations Human Development Index on wealth measured as GDP per capita. We fit one linear model, one quadratic model and one log transformed model. We then make predictions including confidence intervals and add them to the data set. We then plot the results using ggplot.

We need some additional data manipulation skills which we will cover as we go along. Specifically, we select a subset of the data set and we reshape the data set into long format.

```
# drop missings
world.data <- world.data[!is.na(world.data$wdi_gdpc) & !is.na(world.data$undp_hdi), ]

# run regressions
m1 <- glm(undp_hdi ~ wdi_gdpc, data = world.data, family = "gaussian")
m2 <- glm(undp_hdi ~ poly(wdi_gdpc,2), data = world.data, family = "gaussian")
m3 <- glm(undp_hdi ~ log(wdi_gdpc), data = world.data, family = "gaussian")

# make predictions
preds1 <- predict(m1, se.fit = TRUE)
preds2 <- predict(m2, se.fit = TRUE)
preds3 <- predict(m3, se.fit = TRUE)</pre>
```

```
## add point estimates and CIs to the world.data data set
# model 1
world.data$bestguess1 <- preds1$fit</pre>
world.data$lowerbound1 <- preds1$fit - 1.96 * preds1$se.fit
world.data$upperbound1 <- preds1$fit + 1.96 * preds1$se.fit</pre>
# model 2
world.data$bestguess2 <- preds2$fit</pre>
world.data$lowerbound2 <- preds2$fit - 1.96 * preds2$se.fit</pre>
world.data$upperbound2 <- preds2$fit + 1.96 * preds2$se.fit</pre>
# model 3
world.data$bestguess3 <- preds3$fit</pre>
world.data$lowerbound3 <- preds3$fit - 1.96 * preds3$se.fit</pre>
world.data$upperbound3 <- preds3$fit + 1.96 * preds3$se.fit
# selecting a subset of variables
plot.data <- select(world.data,</pre>
                     "undp hdi",
                     "wdi_gdpc",
                     "bestguess1", "lowerbound1", "upperbound1",
                     "bestguess2", "lowerbound2", "upperbound2",
                     "bestguess3", "lowerbound3", "upperbound3")
# reshaping the data set
plot.data <- reshape(plot.data, direction = "long",</pre>
        varying = c("bestguess1","lowerbound1","upperbound1",
                     "bestguess2", "lowerbound2", "upperbound2",
                     "bestguess3", "lowerbound3", "upperbound3"),
        timevar = "Model",
        times = c("1","2","3"),
        v.names = c("bestguess","lowerbound","upperbound"),
        idvar = c("undp_hdi", "wdi_gdpc"))
# renaming the rownames of the data set
row.names(plot.data) <- seq(1:nrow(plot.data))</pre>
# changing the grouping id into a factor
plot.data$Model <- factor(plot.data$Model, levels = c(1,2,3), labels = c("Linear", "Quadratic", "Log"))</pre>
ggplot(plot.data, aes(x = wdi_gdpc, y = undp_hdi)) +
    geom_point(alpha = 0.6, color = "black") +
    geom_line( aes( y = bestguess, color = Model), size = 1, alpha = 0.8) +
    geom_ribbon( aes( ymin = lowerbound, ymax = upperbound, fill = Model), alpha = 0.25 ) +
    labs( x = "GDP per capita", y = "Human Development Index",
          title = "Relationship between wealth and quality of life")
```

2.1.3 Renaming variables and selecting subsets

You may remember that renaming variables involved sub-setting and the logical evaluations. Well, this is one of the things that is quite easy to do in tidyverse. Here, we use the rename() function from the dplyr package.

Let's go back to the eu data set and rename the following variables:

- 1. NUTSO into country
- 2. region_name into region
- 3. econ_2gdp_eur_hab into wealth
- 4. eqi_eqi into quality.of.government

Selecting a subset is as easy as renaming. The function select() lets us do this easily.

```
[1] "country" "region" "wealth"
```

[4] "quality.of.government"

Let's remove our small data set eu.renamed.

```
rm(eu.renamed)
```

We can rename and select in one step within the select() function.

```
country
                                            year
                                                          wealth
                      region
Length: 13884
                   Length: 13884
                                       Min.
                                              :1990
                                                      Min.
                                                            : 1300

2.1.4 Aggregating and pipes

Our data set is on the region-year level. We want to compare countries over time. Therefore, we now aggregate our data up to the country-year level. Note that you want data in the most dis-aggregated fashion possible because aggregating to the next higher level is easy. We want to average over the regions within each country and year.

To do this we introduce two new functions and one new concept. The new concept is called the pipe and its operator is %>%. In our example we say first create a copy of the data set called eu called eu.country.year. We do not stop here but we continue on indicated by the pipe operator %>%. We then group the data set by two variables with the group_by() function. The first variable that indentifies groups is the country and the second is the year. We then continue on with the pipe operator %>% and finally we summarize the data within the groups using the summarize() function.

```
# A tibble: 15 x 4

```

It turns out that we have a lot of missing data in our dataset. Our goal is to plot wealth over time. We have all the necessary parts to do this but we would like to also add an EU average. In other words, for each year we need to create a new observation that receives the value EU for the country variable and the average of wealth within that year and the average of quality of government within that year. We follow the same procedure as previously.

We now have two datasets which need to combine.

2.1.5 Merging data sets

We cannot just paste the data sets together because they differ in the number of columns. As a first step, we need to create a new variable in the data set eu.year called country which identifies the country in that data set.

```
eu.year$country <- "EU"
eu.year
```

```
# A tibble: 26 x 4
    year wealth quality.of.government country
   <int>
           <dbl>
                                  <dbl> <chr>
   1990
 1
             NaN
                                     NaN EU
 2
   1991
                                     NaN EU
             NaN
 3
    1992
             NaN
                                     NaN EU
 4
    1993
             NaN
                                     NaN EU
 5
    1994
             NaN
                                     NaN EU
 6
   1995
            NaN
                                     NaN EU
7
    1996
            NaN
                                     NaN EU
8
    1997
             NaN
                                     NaN EU
9
    1998
             NaN
                                     NaN EU
10
    1999
            NaN
                                     NaN EU
# ... with 16 more rows
```

We now merge the two variables together. Recall that observations are uniquely identified by the variables country and year. We need to order the observations in both data sets before merging. To do this we use the arrange() function from the dplyr package. The datasets are already ordered by the country first and the year second. Let's reorder by year first and then country to illustrate how the function works.

```
eu.country.year <- arrange(eu.country.year, year, country)
eu.year <- arrange(eu.year, year, country)
head(eu.country.year, n = 20)</pre>
```

```

```

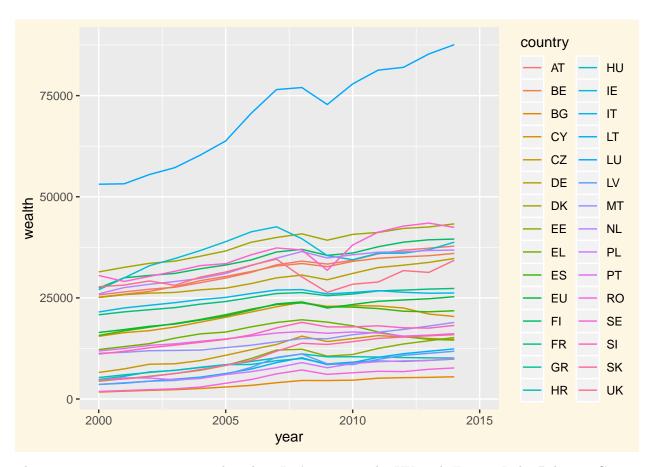

We are ready to merge. To do so, we use the merge() function. We have the same variables in both data sets and both are unique observations. In this case, an alternative to using merge() is to simply bind the data sets together row-wise like so: rbind(eu.country.year, eu.year). However, the nice side-effect of using merge() is that our order by years and then countries remains intact. So the first two arguments of merge() are the names of the data sets to merge. We then specify the variables to merge by in the by argument and finally we need to say keep all observations that are unique to either data set with all = TRUE.

```
eu.join <- merge(eu.country.year, eu.year, by = intersect(names(eu.country.year), names(eu.year)), all
```

Now, you should be able to plot wealth over time on your own. The plot should show the all "countries" in the data set. We do not have data before 2000, so there is no point in plotting it.

```
ggplot(eu.join[eu.join$year>1999,]) +
   geom_line(mapping = aes( x = year, y = wealth, col = country))
```

Warning: Removed 45 rows containing missing values (geom_path).

There are too many countries in this plot. Let's compare the UK with France, Italy, Belgium, Greece, Germany, and Spain. To do this, we use the filter() function. We also take the opportunity to filter out the missing years.

eu.join.small <- filter(eu.join, country %in% c("UK", "FR", "IT", "BE", "EL", "DE", "ES") & year > 1999 & yea head(eu.join.small, n = 20)

	country	year	wealth	quality.of.government
1	BE	2000	25200.00	NaN
2	BE	2001	25900.00	NaN
